# Assessing the Consistency of Average Student Growth Using a Split Classroom Approach 

Neal Kingston<br>University of Kansas<br>Fei Gu<br>McGill University<br>Wenhao Wang<br>Hongling Lao<br>University of Kansas

## Introduction

The United States Department of Education is promoting the use of student growth on summative assessments as part of teacher evaluation. As in any measurement model there are multiple sources of error variance that in this case will detract from our ability to assess the true average student growth attributable to a teacher.

In this study, using data from a state testing program, the reliability of average student growth attributable to teachers was assessed in two ways: within year and across years. Within year all children are taught by a teacher in the same classroom(s) in a given year. Their current year test scores are compared with their previous year scores (when they typically had different teachers). Each class is divided into random halves and the two average student growth scores are calculated for each teacher and those scores are correlated across teachers with the same class size (class size will affect the reliability of average class growth similar to how test length affects test score reliability). We call this the split-class method. In order to calculate cross-year correlations, an average student growth score was calculated for each teacher based on all students' growth scores of each teacher from 2010 to 2011 and then again from 2011 to 2012, and the two cross-year growth scores of all teachers are correlated within a similar range of class sizes.

The sources of error variance are different with these two designs. In the first design, within each classroom there is no variation in how the class is taught. In a cross-years design the teacher or school might make changes to instruction or curriculum from one year to another. Similarly there is no differential variation in teacher health, personal circumstances, or attitudes in the split-class design, but might be in the cross-years design. In addition, the makeup of the classroom might affect a teacher's ability to facilitate learning from one year to the next in the cross-year design.

In this study we will assess the variance due to within-year and cross-year factors using three different common growth models.

## Review of Literature on a Subset of Student Growth Models

## Simple Gain Model

Operations of the simple gain model are straightforward. Growth is defined as the difference between a student's current and prior score (Auty, Bielawski, Deeter, et al., 2008). It is also called difference scores or gain scores, regarding the differences between prior (pretest) and current (posttest) scores. The actual growth can be further used in growth-to-standard models to determine whether a student's growth is adequate by comparing to target growth (Betebenner, 2009). Furthermore, a group growth can be estimated by aggregating individual difference scores at the teacher, school, or district level.

Since the growth is the difference between current and prior scores, the method requires a vertical scale for meaningful interpretation of the gain. Vertical scaling is the process to place scores onto a common scale for tests that measure the same or similar constructs if the tests do not have a common scale at the beginning. For example, this requirement has led to the adaptation of normalized scores (z scores) within grade level in some cases. Goldschmidt, Choi, and Beaudoin (2012) pointed out that this practice assumes that achievement standards across grades are vertically moderated. However, this vertical scaling practice should be adopted with caution. In a study by Tong and Kolen (2007), they compared 11 scaling methods with both real and simulated data. It showed that the 11 scaling methods were able to retain the general characteristics using simulated data when the assumptions are met. However, for the real data, the 11 methods produced vertical scales that showed decelerating growth from lower to higher grades. For the within-grade variability, different scaling methods produced different results. For instance, the Thurstone method produced enlarging variability over grades, whereas the IRT method produced fluctuating or decreasing variability over grades.

The advantage of this method is that its calculation is simple and transparent. It provides a direct estimate of student growth (Auty, Bielaswski, Deeter, et al., 2008). However, gain scores have been criticized as biased and inherently unreliable from theoretical considerations, as well as empirical studies designed to investigate the reliability of measured gains (e.g., Cronbach \& Furby, 1970; Lord \& Novick, 1968; Lord, 1956, 1963). On the other hand, Rogosa and Willett (1983) demonstrated that the reliability of the simple gain model is respectable when the individual differences in true changes are big enough, which supports Zimmerman and Williams (1982) claims that "gain scores in research can be highly reliable." The reliability of the difference score can be greater than that of the pretest and posttest scores when interperson variability in true change is large (Willett, 1988). Moreover, Willett (1988) also argued that even if the difference scores were always unreliable, this would not necessarily be a problem for the measurement of within-person change. Williams and Zimmerman (1996) tried to examine the reliability and validity of simple gain model from a statistical perspective within the framework of classical test theory. Specifically, Williams and Zimmerman (1996) admitted that many difference scores are unreliable. In practice, however, the reliability of a test score is determined by a number of different factors (e.g., the test construction procedure, the nature of the instrument), and "in this respect a difference between scores is similar".

In terms of validity, Williams and Zimmerman (1996, p.11) argued that the validity of difference scores is higher than formerly believed and "the existence of valid difference scores cannot be ruled out by statistical arguments alone."

This model is flawed by several disadvantages. First, it ignores the role of the school context (Burstein, 1980). Students with the same background tend to cluster in the same school. The clustering effect would potentially bias the aggregated estimates of school effects (Raudenbush \& Willms, 1995). Particularly, estimates are biased when the intraclass correlation between the students and the schools is greater than zero (Aitkin \& Longford, 1986). Second, this model ignores the teacher effect as well. McCaffrey and his colleagues (2009) showed that 50 percent variations of the student scores were explained by the teacher effect in elementary schools, whereas 70 percent variations by the teacher effect in middle schools. Finally, this model ignores the student difference in starting points. Thus, the method is criticized as "growth to nowhere" (Goldschmidt, Choi, \& Beaudoin, 2012).

## Student Growth Percentiles (Colorado Growth Model)

The student growth percentiles (SGP) model is a normative quantification of individual student growth, proposed by Betebenner (2008a). It has been adopted by 12 states, while 13 other states show some interest (Betebenner, 2010a). It requires external criteria to decide whether student growth percentiles as "adequate" or "enough" to reach desired achievement standards. This model describes how typical a student's growth is by comparing his/her current achievement to his/her academic peers with the same previous assessment score. It estimates the probability of observing a student's current achievement conditioned on their prior achievement.

In the SGP model, students are compared with their academic peers (who have the same prior scores) only, regardless of their actual prior scores. It is a conditional status based on students' prior scores. If the student's current score exceeds the scores of most of their academic peers, they have done well in a normative sense, at a high percentile under that conditional distribution (Betebenner, 2011). Similarly, two students with the same percentile score for the current year might not have the same absolute amount of growth if they had different prior test scores. A student's current year score is situated normatively as a student's growth percentile at time $t$ taking into account student performance at time 1 , 2 , ..., up to $t-1$. Because the SGP model requires a large amount of data to generate sufficient coverage across the percentiles, Betebenner (2009, 2010b) also developed method to smooth the conditional distribution when sample size is not big enough.

In reality, students are nested within schools such that group level aggregation is involved. Betebenner (2008b) recommended the use of the median as a "typical" student to represent the growth of all students at the school. Due to the ordinal nature of percentile ranks, means are inappropriate to use because it assumes an interval scale underlying the averaged unites. However, Castellano and Ho (under review) argued that strict equalinterval properties are rare and the inferences and properties of means may be useful even when scales are quasi-interval. By contrasting the median and mean SGP models with two
real statewide data, they found four percentile ranks dissimilarity for a school's ranking between these two aggregation functions, at worst with 30 percentile ranks difference.

The first advantage of the SGP model is that scores across years are not required to be vertically scaled, even though contiguous prior test scores are generally required for the SGP model (Goldschmidt et al., 2012). On the other hand, Castellano and Ho (under review) argued that a vertical scale may be required to make growth inferences. The second advantage is that it is more robust to outliers than OLS regression (Betebenner, 2011), despite the fact that they may also be affected by outliers, and sometimes estimating extreme conditional quantiles is required. Third, SGPs are described to be invariant to monotonic transformations of the test scales, supported by Briggs and Betebenner's (2009) study of the scale invariance of SGPs at the aggregate level.

Finally, other advantages include that the normative interpretation of student growth is easy for stakeholders to understand, and it is easy to aggregate individual data to higher units (e.g., teachers and schools). However, more properties of SGPs are to be further explored, such as sensitivity of SGPs to spline parameterization, bias and invariance under various sample sizes and covariate inclusion decisions, as suggested by Castellano and Ho ( under review).

## ANCOVA Model

The analysis of covariance (ANCOVA) model is designed to separate the effects of confounding variables from the interested treatment effect on the dependent variables. The covariate adjusted model can show the posttest difference among students who had the same pretest score (Goldschmidt, Choi, \& Beaudoin, 2012). This model does not provide results in terms of growth as that in simple gain model. Instead, it intends to address explicitly the current student achievement accounting for differing prior achievement (Wright, 2008), and establish associations between students' average conditional status and classroom/school membership (Castellano \& Ho, under review).

Student's current achievement is affected by many factors (e.g., ability, socioeconomic status [SES], motivation), in addition to teacher and school effect. ANCOVA is thus adopted to separate the effects of different covariates (e.g., SES, ability which is indicated by prior achievement) on the variable of interest (e.g., teacher, school effect). It is worth noting that the estimation procedure in random effect models assumes that there is no correlation between group-level effects and student prior scores (Castellano \& Ho, under review). Although this assumption is usually violated in practice, random-effect models are often used in the value-added model (VAM) (Kim \& Fees, 2006). In fact, ANCOVA is a popular tool for the VAM, which assesses how much students have learned during a time frame instead of how much they know at a specific point (status model). It is obvious there is a distinction between the intention/function of ANCOVA and the purpose of VAM. Wright (2008) explicitly pointed out the danger of using ANCOVA in VAM.

One advantage of the ANCOVA model is that it does not require a vertical scale as simple gain model does. It is more robust to either vertical or non-vertical scales (Wright,
2008). In addition, it estimates individual achievement and group level effect (i.e., teachereffect) simultaneously.

If the covariate is measured with error, the ANCOVA model is likely to produce biased results (McCaffrey et al., 2004). More specifically, Wright (2008) pointed out that the negative consequences include (1) the estimated slope is biased toward zero; (2) the estimated teacher effects are biased toward the value that is estimated in a status model instead of a VAM; (3) the estimated teacher effects would be highly correlated with students' socioeconomic status. Generally, to ameliorate the bias in estimates, including multiple prior assessment scores (the same subject and other subjects as well) into the model is an effective method (Wright, 2008).

## Methods

This study compares the consistency of ranking teachers using growth scores obtained from the three different growth models just described. First, teachers' growth scores in 2011 and 2012 were calculated, and the correlation between teachers' growth scores in these two years was used as a measure of the between-year consistency. Second, a teacher's growth score based on half of his/her students (randomly selected) was calculated such that two growth scores can be obtained from the two halves for the same teacher. In other words, there are two growth scores for each teacher within every year. Then, the correlation can be calculated between the two growth scores across teachers. This correlation, called the half-class correlation, was used to investigate the within-year reliability. Moreover, the number of students is varying across teachers, which may affect the teacher's growth score and thus the between- and within-year correlations. Herein, the between- and within-year correlations will be calculated using the teacher's growth scores from) all available teachers, and 2) different subsets of teachers who have a pre-specified number of students. In this section, the assessments, sample, and three models used for calculating growth scores will be introduced.

## The Assessments

Summative assessments from 2009 to 2012 from one state assessment program were used to calculate the average student growth scores for teachers of $7^{\text {th }}$ grade mathematics and English language arts. All items in these assessments were multiplechoice items with four options. The summative assessment scores across years are not vertically scaled. The simple gain model and the student percentile growth model use the summative assessment scores from two consecutive years, whereas the ANCOVA model use summative assessment scores from three consecutive years. Particularly, for a teacher who taught grade 7 math in the 2011-2012 academic year, his or her students' end-of-year summative math assessment scores from grade 7 (2012), 6 (2011), and 5 (2010) were used in the ANCOVA model to calculate this teacher's growth scores in 2012; and for a teacher who taught grade 7 reading in the 2010-2011 academic year, his or her students' end-ofyear summative reading assessment scores from grade 7 (2011), 6 (2010), and 5 (2009) were used in the ANCOVA model to calculate this teacher's growth scores in 2011.

## The Sample

Students who took end-of-year summative assessments each of three consecutive years (2009, 2010, and 2011 or 2010, 2011, and 2012) and whose teacher information is present were included in the sample. Table 1 shows the number of students and teachers in each grade and subject sample for the 2011-2012 and 2010-2011 academic year growth score calculation.

Table 1. Total number of students and teachers for each subject and year

| Test and Year | Students | Teachers |
| :--- | :---: | ---: |
| Math 2012 | 31,202 | 920 |
| Math 2011 | 30,985 | 915 |
| Reading 2012 | 31,369 | 1,005 |
| Reading 2011 | 31,309 | 1,098 |

## The Models

Three models are considered in this paper. The first model is the simple gain model. It calculates the student growth score by differencing the end-of-year assessment scores from two consecutive years. The students who took two end-of-year summative math or reading assessments (either from 2011 and 2012 or from 2010 and 2011) are included. Since the end-of-year summative assessment score is not vertically scaled across years, the scores are first normalized (transformed to z-scores by student ranking) to overcome the non-comparability shortcoming of this model. The student simple gain growth score is:

$$
\operatorname{Gain}_{i}=Z(Y)_{i t}-Z(Y)_{i(t-1)}
$$

where $Z(Y)_{i t}$ is the normalized assessment score for student $i$ at time $t(t=2012,2011)$. Then, the teacher growth score is calculated by averaging the growth scores of all his or her students.

The second model is the student growth percentile model. Since only two end-ofyear summative assessment scores are needed, the students who took two end-of-year summative math or reading assessments (either from 2011 and 2012 or from 2010 and 2011) are used in this model. To calculate the growth percentile of a student, his or her end-of-year summative assessment in the previous year is chosen as a conditioning variable. Percentile ranks are calculated for current year scores for the group of students who had the same scores the previous year. Finally, a teacher's growth score is the median of the growth percentiles of all his or her students. Vertical scaling is not necessary for this model.

The third model is the analysis of covariance (ANCOVA).The covariates in this model are the two previous end-of-year summative assessments, controlling for the student's previous ability. Students who took all three end-of-year summative math or reading assessments (either from 2010, 2011 and 2012 or from 2009, 2010 and 2011) are included in the analyses for this model. The ANCOVA model is formulated as

$$
Y_{i t}=\beta_{0}+\beta_{1} Y_{i(t-1)}+\beta_{2} Y_{i(t-2)}+\boldsymbol{\beta} \text { TeacherID }+\varepsilon_{i},
$$

where $Y_{i t}, Y_{i(t-1)}$, and $Y_{i(t-1)}$ are summative assessment scores for student $i$ at time $t(t=$ 2012, 2011); $\beta_{0}$ is the intercept representing the growth score of the reference teacher ${ }^{1}$

[^0]when two previous assessment are $0 ; \beta_{1}$ and $\beta_{2}$ are the coefficients for the two covariates; Teacher ID is categorical variable and $\boldsymbol{\beta}$ is the coefficient vector including the coefficients associated with teacher categories in the TeacherID vector; $\varepsilon_{i}$ is the random error for student $i$. A teacher's growth score is calculated as the sum of the intercept and his or her teacher category coefficient.

## Modeling the Relationship between Correlations and Number of Students in Sample

With the relatively small number of teachers whose average student scores were compared, correlations are not estimated with great stability. To reduce the noise associated with this issue, correlations were Fisher-Z transformed and then regressed on the natural log of class size. This logarithmic relationship was chosen to reflect the ceiling effect of the regression of correlations of average growth with class size. While correlations of average growth are expected to increase with class size (since the means are estimated more accurately in larger classes), but are limited to 1.0, this relationship seemed appropriate, though other functional forms might also be reasonable.

Correlations based on very small samples are highly variable. For example, for any class size that has only two teachers, correlations will be either positive one or negative one. Moreover, since the very low and very high class sizes are less common, these cases will have extreme influence when estimating regression coefficients. Therefore, for the split-class method class sizes with fewer than 10 teachers were omitted from the modeling of the relationship between class size and correlation.

For the cross-year method too many cases had fewer than 10 teachers so a different approach was used. Correlations were averaged for 5 ranges of sample sizes and the midpoint of the class sizes was used in the regression.

Results of these analyses can be found in Appendix E.

Using the regression equation for each model, predicted Fisher-Z transformed correlations were estimated for sample sizes of 10 to 100 and transformed back to the correlation metric.

## Results

Appendices A and B present the correlations for the split-class method for Mathematics and Reading, respectively. There are two entries (in subsequent rows) for most half-class size: one from 2011 and one from 2012.

Appendices C and D present similar information for the cross-years method.
Appendix E show the regressing of Fisher-z transformed correlations for the three student growth models based on the split-class and cross-year methods for both mathematics and reading. Cross-year regressions are based on grouped class-size data and the middle of the range of class sizes is listed.

Table 2 presents the estimated correlations for different mathematics and reading class sizes based on the split-class data. For mathematics, correlations are about the same for the three growth models, with the ANCOVA model performing as well or slightly better than the other two methods at each class size. For reading the improvement with the ANCOVA model was greater. Since the ANCOVA model uses more data than the other two models its superior performance is not surprising.

Table 2. Predicted Reliability of Average Growth Scores at Different Sample Sizes based on the Split-Class Method

| Number <br> of Students | Mathematics |  |  | Reading |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Simple Gain Scores | Student Growth Percentiles | ANCOVA | Simple Gain Scores | Student Growth Percentiles | ANCOVA |
| 10 | 0.72 | 0.74 | 0.78 | 0.52 | 0.52 | 0.58 |
| 15 | 0.79 | 0.80 | 0.83 | 0.59 | 0.58 | 0.65 |
| 20 | 0.83 | 0.83 | 0.86 | 0.63 | 0.62 | 0.70 |
| 25 | 0.85 | 0.85 | 0.88 | 0.66 | 0.64 | 0.73 |
| 30 | 0.87 | 0.86 | 0.89 | 0.68 | 0.67 | 0.75 |
| 40 | 0.90 | 0.89 | 0.91 | 0.71 | 0.70 | 0.78 |
| 50 | 0.91 | 0.90 | 0.92 | 0.74 | 0.72 | 0.81 |
| 60 | 0.92 | 0.91 | 0.93 | 0.76 | 0.74 | 0.82 |
| 70 | 0.93 | 0.92 | 0.94 | 0.77 | 0.76 | 0.84 |
| 80 | 0.94 | 0.92 | 0.94 | 0.78 | 0.77 | 0.85 |
| 90 | 0.94 | 0.93 | 0.95 | 0.79 | 0.78 | 0.86 |
| 100 | 0.95 | 0.93 | 0.95 | 0.80 | 0.79 | 0.86 |

There is no clear-cut rule for how reliable a measure should be, but for most professionally developed assessments used to make important decisions about students reliability estimates are in the $.90-.95$ range. And even with reliabilities in that range professional testing standards say that multiple measures should be used for important decisions. For mathematics a split-class correlation of 90 is attained when average student growth scores are based on 40 or more students. For reading a .90 correlation is not reached even with 100 students.

Table 3 presents the estimated correlations for different mathematics and reading class sizes based on the cross-years data. For mathematics, the student growth percentiles method and the ANCOVA method performed about the same and outperformed the simple gain score method (especially for small class sizes). For reading the ANCOVA model performed better than the student growth percentiles method which in turn performed better than the simple gain scores method. It is particularly important to note that all methods showed much lower reliability using the cross years method. No method at any reported sample size had a reliability near.90. If the method used for predicting reliability based on sample sizes holds for significantly larger samples, it would require a teacher to have data from 11,464 students to achieve a reliability of .90 using the ANCOVA method. Clearly the additional variability associated with the same teacher's student average growth across years is a significant factor.

Table 3. Predicted Reliability of Average Growth Scores at Different Sample Sizes based on the Cross-Year Method

| Number <br> of <br> Students | $\|c\|$ | Simple <br> Gain <br> Scores | Student <br> Growth <br> Percentiles | ANCOVA | Simple <br> Gain <br> Scores | Student <br> Growth <br> Percentiles |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 0.19 | 0.39 | 0.36 | 0.22 | 0.33 | ANCOVA |$|$| 15 | 0.28 | 0.45 | 0.43 | 0.27 |
| :---: | :---: | :---: | :---: | :---: |
| 20 | 0.34 | 0.49 | 0.47 | 0.30 |
| 25 | 0.39 | 0.51 | 0.50 | 0.33 |
| 30 | 0.43 | 0.54 | 0.53 | 0.35 |
| 40 | 0.48 | 0.57 | 0.57 | 0.38 |
| 50 | 0.52 | 0.60 | 0.60 | 0.41 |
| 60 | 0.55 | 0.61 | 0.62 | 0.43 |
| 70 | 0.57 | 0.63 | 0.64 | 0.43 |
| 80 | 0.59 | 0.64 | 0.65 | 0.44 |
| 90 | 0.61 | 0.66 | 0.66 | 0.46 |
| 100 | 0.63 | 0.67 | 0.67 | 0.47 |

## Discussion

Determining the fairness of a teacher evaluation system based in part or exclusively on the performance of that teacher's students is complex. Within-year variance estimated by the split-class method is largely due to variability in individual students, but may also be due in part to a particular teacher's ability to connect to some but not all students. Cross year variance estimated by the cross-years method includes the variance due to within year influences, but also includes other sources of variability in student growth, some of which might not be reasonably under teacher control.

Once can partition the variance associated with teacher evaluation scores based on student growth into true variance and multiple sources of error variance. The squared reliability tells us the proportion of true variance. The remaining variance is error associated with one or more factors. Using the ANCOVA growth model and a class size of 100 (the equivalent of a grade 7 mathematics teacher teaching four 25 student sections), the split-class correlation of .95 and cross-years correlation of .67 indicate $45 \%$ of the variability of teacher evaluation scores (assuming they are based on only student average growth) would be due to long-term teacher quality, $45 \%$ would be due to cross-year variability in student performance, and $10 \%$ would be due to the sample of students. A similar analysis for Reading raises even greater concerns, with $40 \%$ of the variability of teacher evaluation scores due to long-term teacher quality, $34 \%$ due to cross-year variability in student performance, and $26 \%$ due to the sample of students.

The second of the three sources of variability in the previous paragraph, cross-year variance, might or might not be under teacher control, but even if it is there are policy considerations. With a cross-year correlation of .7 , which is higher than we see for any of the reading models for a teacher whose evaluation score is based on 100 students, $40 \%$ of the teachers who are evaluated as being in the top-quarter of all teachers one year will be evaluated as being outside the top-quarter the subsequent year. Moreover, $2 \%$ of those teachers who were in the top-quarter one year will be in the bottom quarter the next. This type of year-to-year variation in teacher ratings may raise questions of credibility for any such system.
